Abstract

The chromatic number of a Latin square is the least number of partial transversals which cover its cells. This is just the chromatic number of its associated Latin square graph. Although Latin square graphs have been widely studied as strongly regular graphs, their chromatic numbers appear to be unexplored. We determine the chromatic number of a circulant Latin square, and find bounds for some other classes of Latin squares. With a computer, we find the chromatic number for all main classes of Latin squares of order at most eight.

Keywords: Transversal, Partial transversal, Latin square, Latin square graphs, Net graphs, Coloring, Cayley table, Orthogonal array, Orthogonal Mate.

2000 MSC: 05B15- 05C15

1. Introduction and preliminaries

Let $L$ be a Latin square of order $n$. The chromatic number of $L$, denoted by $\chi(L)$, is the minimum number of partial transversals of $L$ which together cover the cells of $L$. Since each partial transversal uses at most $n$ of the $n^2$ cells in $L$, we observe the following.

**Proposition 1.** Every Latin square $L$ of order $n$ satisfies $\chi(L) \geq n$, with equality holding if and only if $L$ has an orthogonal mate.

Therefore $\chi(L)$ serves as a measure of how close $L$ is to having an orthogonal mate. We are surprised that this natural invariant appears not to been stud-
ied, despite the substantial interest and existing literature regarding transver-
sals and orthogonality of Latin squares. In this paper, we find some bounds
on $\chi(L)$ for general Latin squares and special classes such as complete Latin
squares, Cayley tables of groups, circulants, and all Latin squares of order at
most eight.

For the definitions not given here one may refer to [1] and [4]. Let $L$
be a Latin square of order $n$ with cells $\{(r, c) \mid r, c \in \{0, 1, 2, \ldots, n - 1\}\}$;
each cell contains a symbol from an alphabet of size $n$, and no row or column
of $L$ contains a repeated symbol. A cell $(r, c)$ containing the symbol $s = L_{r,c}$
is sometimes represented by the triple $(r, c, s)$. A partial transversal of
length $k$ is a set of $k$ cells, where no two cells have the same row, column or
symbol. A transversal is a partial transversal of length $n$. The Latin square $L$
has an orthogonal mate if and only if it has a decomposition into disjoint
transversals. We say that $L$ is row-complete if every ordered pair of distinct
symbols appears (exactly once) in the set

$$\{(s, s') \mid (r, c, s), (r, c + 1, s') \in L, \text{ for } 0 \leq r \leq n - 1 \text{ and } 0 \leq c \leq n - 2\}.$$ 

The Latin square graph of $L$ is the simple graph $\Gamma(L)$ whose vertices are
the cells of $L$, and where distinct cells $(r, c, s)$ and $(r', c', s')$ are adjacent if either
$r = r'$, $c = c'$ or $s = s'$. Accordingly, each edge of $\Gamma(L)$ is either a row edge,
a column edge or a symbol edge. Latin square graphs were introduced by R. C. Bose [2]
as examples strongly regular graphs; see [8, Section 10.4] for further discussion. Bose used the notation $L_3(n)$ for this graph. But this notation does not carry the Latin square of which it is originated. So we use
the notation $\Gamma(L)$ for the graph corresponding to the given Latin square $L$.

The independent sets of $\Gamma(L)$ are the partial transversals of $L$, and $\chi(L)$
is the chromatic number of $\Gamma(L)$. The isomorphism class of $\Gamma(L)$ is not
affected by relabeling the rows, columns or symbols of $L$, nor is it changed
by applying a fixed permutation the coordinates of every triple $(r, c, s)$ in $L$.
Thus $\chi(L)$ is an invariant of the main class of $L$.

Let $(G, \circ)$ be a finite group of order $n$. A Cayley table for $G$ is an $n \times n$
matrix, denoted $L_G$, where the cell $(i, j)$ contains the group element $g_i \circ g_j$,
for some fixed enumeration $G = \{g_0, \ldots, g_{n-1}\}$. It is easy to see that $L_G$
is a Latin square. If $G$ is a cyclic group, then $L_G$ is called a circulant Latin
square. Figure 1 shows the graph of the circulant $L_{\mathbb{Z}_3}$.

We summarize the results of this paper. Let $L$ be a Latin square of order
$n$.
• $n \leq \chi(L) \leq 3n - 2$.

• If $L$ is row-complete, then $\chi(L) \leq 2n$.

• For large $n$ we have $\chi(L) = n + o(n)$.

• For every group $G$ of order $n$, either $\chi(L_G) = n$ or $\chi(L_G) \geq n + 2$.

• If $L$ is a circulant (that is $L \cong L_{\mathbb{Z}_n}$), then $\chi(L) = \begin{cases} n & \text{if } n \text{ is odd} \\ n + 2 & \text{if } n \text{ is even.} \end{cases}$

• If $n \leq 8$, then 

$$\chi(L) \leq \begin{cases} n + 1 & \text{if } n \text{ is odd} \\ n + 2 & \text{if } n \text{ is even.} \end{cases} \tag{1}$$

For lack of a counterexample, we ask the following.

**Question 1.** Does (1) hold for every Latin square $L$?

An affirmative answer to Question 1 would surely be challenging to prove, even for Cayley tables of groups. Since $(n+1)(n-1) < n^2$ and $(n+2)(n-2) < n^2$, every Latin square $L$ which satisfies (1) must have a transversal (if $n$ is odd) or a partial transversal of length $n - 1$ (if $n$ is even). So the truth of Question 1 would imply two longstanding conjectures of Brualdi-Stein and Ryser.

**Conjecture 1.** ([5, 14]) Every Latin square of even order $n$ contains a partial transversal of size $n - 1$.

**Conjecture 2.** ([13]) Every Latin square of odd order contains a transversal.
2. Some Upper Bounds

The graph of a Latin square $L$ of order $n$ is regular of degree $3n - 3$. This immediately gives $\chi(L) \leq 3n - 2$. We can improve this bound in case $L$ has additional structure.

A $k$-plex is a set of $kn$ cells which has $k$ representatives from each row and each column and each symbol of $L$. A $(k_1, k_2, \ldots, k_d)$-partition is a partition $K_1, K_2, \ldots, K_d$ were each $K_i$ is a $k_i$-plex.

**Proposition 2.** If a Latin square $L$ of order $n$ has a $(k_1, k_2, \ldots, k_d)$-partition, then $\chi(L) \leq 3n - 2d$.

**Proof.** Let $K_1, K_2, \ldots, K_d$ be a $(k_1, k_2, \ldots, k_d)$-partition of $L$. For each $i$, the induced subgraph $\Gamma(L)[K_i]$ is regular of degree $3k_i - 3$, so it is $(3k_i - 2)$-colorable. Thus, $\chi(L) \leq \sum_{i=1}^{d} (3k_i - 2) = 3n - 2d$. ■

Wanless [15, 16] has conjectured that every Latin square of order $n$ has a $(k_1, k_2, \ldots, k_d)$-partition where $d \geq \lfloor \frac{n}{2} \rfloor$. If true, his conjecture would improve the general upper bound to $\chi(L) \leq 2n + 1$.

**Corollary 1.** Let $t$ be the number of maximum disjoint transversals in a Latin square $L$ of order $n$. Then

$$\begin{cases} 
\chi(L) \leq 3n - 2t - 2 & \text{if } t \leq n - 2 \\
\chi(L) = n & \text{otherwise.}
\end{cases}$$

A Latin square $L$ of order $n$ is *row-complete* (sometimes it is called a Roman square) if the ordered pairs $(L_{i,j}, L_{i,j+1})$ are all distinct for $0 \leq i \leq n - 1$ and $0 \leq j \leq n - 2$. Row-complete Latin squares are used in the design of sequential experiments [5].

**Proposition 3.** If $L$ is a row-complete Latin square of order $n$, then $\chi(L) \leq 2n$.

**Proof.** We color each cell $L_{i,j}$, $0 \leq i \leq n - 1$ and $0 \leq j \leq n - 2$, with the entry of $L_{i,j+1}$. By the definition of row-complete, the cells with color $c$ are a partial transversal in $L$. We color the last column of $L$ with $n$ new colors. This gives $\chi(L) \leq 2n$. See Figure 2 for an example. ■

The above bounds are far from optimal for large Latin squares. Let $V$ be the disjoint union $R \cup C \cup S$ where $R$, $C$, $S$ is the set of rows, columns,
and symbols of a Latin square $L$ of order $n$. Let $H = (V, E)$ be the 3-uniform 3-partite hypergraph, where there is a hyperedge $\{r, c, s\} \in E$ for every cell $(r, c, s) \in L$. Then $H$ is a linear hypergraph i.e., no two hyperedges share more than one vertex, and $H$ is regular of degree $n$. Also $\chi(L)$ is the chromatic index of $H$, the least number of colors needed to color $E$ so that no two adjacent hyperedges get the same color. The following general result of Molloy and Reed [11] implies an asymptotically optimal bound for $\chi(L)$.

**Theorem 1.** For every $k$ there exists a constant $c_k$ such that every $k$-uniform linear hypergraph of maximum degree $n$ has chromatic index at most $n + c_k(\log n)^{4n^{1-1/k}}$.

**Corollary 2.** As $n \to \infty$ every Latin square $L$ of order $n$ satisfies $\chi(L) \leq n + o(n)$.

### 3. Chromatic Number of Cayley Tables

The set of finite groups $G$ for which $\chi(L_G) = |G|$ has been recently characterized.

**Theorem 2.** For any finite group $G$ of order $n$ with identity element $\epsilon$, the following are equivalent.

1. $\chi(L_G) = n$
2. $\chi(L_G) \leq n + 1$.
3. $L_G$ has a transversal.
4. For some enumeration $g_1, g_2, \ldots, g_n$ of $G$ we have $g_1g_2\ldots g_n = \epsilon$.
5. Every Sylow 2-subgroup of $G$ is either trivial or non-cyclic.

**Proof.** The equivalence of statements 1. and 3. is classic, while the equivalence of 4. and 5. was shown in [6]. The equivalence of 3. and 4. was conjectured by Hall and Paige [9], and proved by Bray, Evans and Wilcox.
Corollary 3. We have

1. $\chi(L_G) = |G|$ for every group $G$ of odd order (also see [3]).
2. For every group $G$ of order $n$, either $\chi(L_G) = n$ or $\chi(L_G) \geq n + 2$.
3. Let $G$ be an Abelian group of order $n$, $\chi(L_G) \geq n + 2$ if and only if $G$ has a unique element of order 2 (also see [12]).

The rest of this section is devoted to proving that the lower bound of Corollary 3(3.) is tight for cyclic groups.

Theorem 3. For $n \geq 1$ the circulant Latin square of order $n$ satisfies

$$
\chi(L_{\mathbb{Z}_n}) = \begin{cases}
  n & \text{if } n \text{ is odd} \\
  n + 2 & \text{if } n \text{ is even.}
\end{cases}
$$

Our proof of Theorem 3 utilizes the following class of graphs.

Definition. The Möbius ladder of order $2n$ is the cubic graph $M$ obtained from a cycle $C$ of length $2n$ by adding $n$ new edges, each connecting an opposite pair of vertices of $C$. The cycle $C$ is called the rim of $M$, and the added edges are called the rungs of $M$. (See Figure 3 and Figure 4(b)). Two vertices of $M$ are said to be nearly antipodal in $M$ if they are at distance $n - 1$ in $C$.

The following proposition is straightforward to verify.

Proposition 4. If $x$, $x'$ are nearly antipodal vertices of a Möbius ladder $M$, then $M - \{x, x'\}$ is bipartite.

Let $L_{\mathbb{Z}_n} = \{(r, c, s) \in \mathbb{Z}_n \times \mathbb{Z}_n \times \mathbb{Z}_n \mid s = r + c \pmod n\}$ be the circulant Latin square of order $n$. For $0 \leq i < n$, we define the $i$th right diagonal of $L_{\mathbb{Z}_n}$ to be the set $T_i = \{(r, r + i, 2r + i) \mid 0 \leq r \leq n - 1\}$.

Proposition 5. For $0 \leq i < n$, the subgraph $\langle T_i \cup T_{i+1} \rangle$ of $\Gamma(L_{\mathbb{Z}_n})$ induced by the 2-plex $T_i \cup T_{i+1}$ is isomorphic to the Möbius ladder of order $2n$. Moreover if $n = 2m$ is even, then every cell $x \in T_i$ is nearly antipodal to each of the cells $x' = x + (m, m + 1, 1)$ and $x'' = x + (m - 1, m, -1)$.
Proof. The row edges and column edges in $\langle T_i \cup T_{i+1} \rangle$ comprise the rim of the Möbius ladder. For each $(r, c, s) \in T_i$, we have $c - r = i$, $c + r = s$, and the only other solution to the system $\{c' - r' \in \{i, i + 1\}, c' + r' = s\}$ (mod $n$) is $(r', c') = (r + \lfloor \frac{n}{2} \rfloor, c + \lceil \frac{n}{2} \rceil)$. Therefore each symbol edge in $\langle T_i \cup T_{i+1} \rangle$ is a rung joining an opposite pair of vertices along the rim of $\langle T_i \cup T_{i+1} \rangle$. If $n = 2m$ and $x \in T_i$, then both $x'$ and $x''$ are nearly antipodal to $x$ since they are adjacent to $x + (m, m, 0)$ along the rim of $\langle T_i \cup T_{i+1} \rangle$, and $\{x, x + (m, m, 0)\}$ is a rung of $\langle T_i \cup T_{i+1} \rangle$.

See Figure 4 for an example.

\end{figure}

Figure 4: For $L_{2n}$, we indicate $T_4 \cup T_5$ in bold face, and underline the near antipodal cells $x = (0, 4, 4)$ and $x'' = x + (3, 4, -1) = (3, 0, 3)$ in the Möbius ladder $\langle T_4 \cup T_5 \rangle$. 

\begin{figure}[h]
Proof of Theorem 3. If $n$ is odd it follows by Corollary 3(1).
If $n$ is even, by Corollary 3(3), it suffices to show that $\Gamma(L_{2m})$ has a proper $(2m + 2)$-coloring for $m \geq 1$. This is true for $m = 1$ since $\Gamma(L_2) \cong K_4$. We assume $m \geq 2$ and let $k = \lceil \frac{m}{2} \rceil$. Using the notation $[t] = \{0, 1, \ldots, t - 1\}$, we define four sets of cells:

$$X = \{x_j \mid j \in [k]\}, \quad X' = \{x'_j \mid j \in [k]\},$$
$$Y = \{y_j \mid j \in [m - k]\}, \quad Y' = \{y'_j \mid j \in [m - k]\},$$

where

$$x_j = (j, 3j, 4j), \quad x'_j = x_j + (d_r, d_c, d_s), \quad \text{for } j \in [k],$$
$$y_j = x_j + (0, 2k, 2k), \quad y'_j = y_j + (d_r, d_c, d_s), \quad \text{for } j \in [m - k],$$

and where

$$(d_r, d_c, d_s) = \begin{cases} (m, m + 1, 1) & \text{if } m \equiv 0 \pmod{3}, \\ (m - 1, m, -1) & \text{if } m \not\equiv 0 \pmod{3}. \end{cases}$$

Each of these sets is (essentially) a translation of $X$:

$$X' = X + (d_r, d_c, d_s), \quad (2)$$
$$Y \cup Y' = \begin{cases} (X \cup X') + (0, 2k, 2k) & \text{if } m \text{ is even}, \\ (X \cup X' \setminus \{x_k, x'_k\}) + (0, 2k, 2k) & \text{if } m \text{ is odd}. \end{cases} \quad (3)$$

See Figure 5 for examples.

Claim: Each of $X \cup X'$ and $Y \cup Y'$ is an independent set in the graph $\Gamma(L_{2m})$.

Proof of Claim: By (3) it suffices to prove the statement for $X \cup X' = \{x_j, x'_j \mid j \in [k]\}$. For any integer $t$, we define $\check{t} \in [2m]$ to be the least positive residue of $t$ modulo $2m$. For $j \in [k]$ we write $x_j = (r_j, c_j, s_j)$ and $x'_j = (r'_j, c'_j, s'_j)$, and define the following six multisets:

$$R = \{r_0, r_1, \ldots, r_{k-1}\}, \quad R' = \{r'_0, r'_1, \ldots, r'_{k-1}\},$$
$$C = \{c_0, c_1, \ldots, c_{k-1}\}, \quad C' = \{c'_0, c'_1, \ldots, c'_{k-1}\},$$
$$S = \{s_0, s_1, \ldots, s_{k-1}\}, \quad S' = \{s'_0, s'_1, \ldots, s'_{k-1}\}.$$
We aim to show that none of $R \cup R', C \cup C', S \cup S'$ has a repeated entry. For $j \in [k]$ each of the numbers $r_j = j$, $c_j = 3j$, $s_j = 4j$ is bounded above by $4(k - 1) < 2m$, so we have

\[
r_j = r_j = j, \quad c_j = c_j = 3j, \quad s_j = s_j = 4j.
\]

Therefore none of the lists $R$, $C$, $S$ has a repeated entry. By (2), none of the lists $R'$, $C'$, $S'$ has a repeated entry, so it suffices to show that each of the sets $R \cap R'$, $C \cap C'$, $S \cap S'$ is empty. First, since $m \geq 2$ we have $k < m$ so $R \subseteq \{0, 1, \ldots, m - 2\}$. For $j \in [k]$ we have $r'_j = r_j + d_r \in \{r_j + m, r_j + (m - 1)\} \subseteq \{m - 1, m, \ldots, 2m - 1\}$. Therefore $r'_j = r'_j$ and $R \cap R' = \emptyset$. Second, for $j \in [k]$ we have $c'_j = c_j + d_c \in \{c_j + (m + 1), c_j + m\}$. Therefore $0 \leq c'_j < 4m$ and

\[
c'_j = \begin{cases} 3j + d_c, & \text{if } c_j + d_c < 2m \\ 3j + d_c - 2m, & \text{if } c_j + d_c \geq 2m. \end{cases}
\]

If $m \equiv 0 \pmod{3}$, then $d_c = m + 1$ so $c'_j \equiv 1 \pmod{3}$. If $m \not\equiv 0 \pmod{3}$, then $d_c = m$ so $c'_j \equiv \pm m \pmod{3}$. In both cases we find $c'_j \not\equiv 0 \equiv c_j \pmod{3}$ for $j \in [k]$. Therefore $C \cap C' = \emptyset$. Third, for $j \in [k]$ we have $s'_j = s_j \pm 1$ so $s_j$ is even and $s'_j$ is odd. Since $2m$ is even, we conclude that $s_j$ is even and $s'_j$ is odd for every $j \in [k]$. Therefore $S \cap S' = \emptyset$ and the claim is proved.
For every $j \in [m]$ we apply Proposition 5 to the 2-plex

$$M_j := T_{2j} \cup T_{2j+1},$$

where $T_i$ is the $i$th right diagonal of $L_{\mathbb{Z}_m}$. Each induced subgraph $\langle M_j \rangle$ is a Möbius ladder. For $j \in [k]$ we have that $x_j \in T_{2j}$, so the cell $x_j' = x_j + (d_r, d_c, d_s)$ is nearly antipodal to $x_j$ in $\langle M_j \rangle$. Similarly, for $j \in [m-k]$ we find that $y_j$ and $y_j'$ are nearly antipodal vertices of $\langle M_{j+k} \rangle$. We now consider the following partition of $L_{\mathbb{Z}_m}$ into $m + 1$ parts.

$$\{ M_j - \{x_j, x_j'\} \mid j \in [k] \} \cup \{ M_{j+k} - \{y_j, y_j'\} \mid j \in [m-k] \} \cup \{ X \cup X' \cup Y \cup Y' \}$$

By Proposition 4 and the above claim, each part induces a bipartite subgraph of $\Gamma(L_{\mathbb{Z}_m})$. We conclude that $\chi(L_{\mathbb{Z}_m}) \leq 2m + 2$.

See Figure 6 for some examples.

Figure 6: Colorings of $L_{\mathbb{Z}_4}$, $L_{\mathbb{Z}_6}$, and $L_{\mathbb{Z}_8}$ by the method of Theorem 3. The colors are given as subscripts.

4. Latin squares of small orders

We have computed $\chi(L)$ for all main classes of order $n$, $2 \leq n \leq 7$. N. Shajari has verified by computer that of all 283657 main classes of Latin squares of order 8 as listed in [10] are 10-colorable. The results are summarized in Table 1.
